

METHOD OF MANUFACTURING A SEMICONDUCTOR DEVICE

CROSS-REFERENCE TO RELATED APPLICATION

The present application claims priority from Japanese patent application JP 2003-097223 filed on March 31, 2003, the content of which is hereby incorporated by reference into this application.

BACKGROUND OF THE INVENTION

The present invention relates to a manufacturing technique of a semiconductor device, and more particularly to a technique which is effectively applicable to steps in which a semiconductor wafer adhered to an adhesive tape is divided into a plurality of semiconductor chips by dicing and, thereafter, the respective semiconductor chips are peeled from the adhesive tape.

Recently, aiming at the high-density packaging of a semiconductor device, a stacked package which three-dimensionally mounts plural sheets of semiconductor chips on a printed wiring board has been put into practice. However, in assembling such a stacked package, the semiconductor chips (hereinafter, simply referred to as "chips") are used which are processed such that a thickness of the each chips is reduced to approximately several tens μm .

In mounting such thin chips on the printed wiring board, first of all, on a main surface of a semiconductor wafer (hereinafter, simply referred to as "wafer") which forms a

desired integrated circuit, a tape which protects the integrated circuit is laminated. In such a state, by polishing or etching a rear surface of the wafer, a thickness of the wafer is decreased to approximately several tens μm . Then, dicing is performed in a state that the adhesive tape is laminated to the rear surface of the thin wafer so as to divide the wafer into a plurality of chips. Thereafter, the rear surface of the adhesive tape is pushed up by the pusher pins and the like to peel the chips one after another from the adhesive tape. The peeled chips are picked up by a collet and are transported to the printed wiring board and pellet-bonding is performed.

Here, in the abovementioned package assembling steps which use the extremely thin chips, when the chips which are divided by dicing are peeled or are picked up from the adhesive tape, cracks or chippings are liable to easily occur on the chips and hence, it is necessary to provide measures to prevent the occurrence of these cracks or chippings.

Japanese Unexamined Patent Publication Hei 6(1994)-295930 discloses a technique which prevents the occurrence of cracks and chippings when the chips are peeled from the adhesive tape. A chip peeling device described in the literature includes a support base which supports an adhesive sheet to which a wafer which is divided into a plurality of chips is adhered, a peeling head which is arranged below the support base, peeling pins which are housed in the inside of the peel head and are constituted of slide pins which rub a back surface of the adhesive sheet and pusher pins which push up the chips,

and drive means which move the slide pins and the pusher pins respectively in the horizontal direction and in the vertical direction.

In peeling the chips from the adhesive sheet using the abovementioned chip peeling device, first of all, the slide pins are brought into contact with back surfaces of portions of the adhesive sheet to which the chips to be peeled are adhered and, thereafter, the slide pins are made to rub the sheet surface while being reciprocated in the horizontal direction so that an adhesive strength between the adhesive sheet and the chips is weakened. Next, by elevating the slide pins and the pusher pins simultaneously so as to lift the chips, the chips having the weakened adhesive strength are peeled from the adhesive sheet without requiring a strong pushing force.

[Patent Document]

Japanese Unexamined Patent Publication No. Hei
6(1994)-295930

SUMMARY OF THE INVENTION

In the abovementioned prior art, the adhesive strength between the adhesive sheet and the chips is weakened by bringing the slide pins into contact with the back surface of the adhesive sheet and by rubbing the adhesive sheet with the slide pins by reciprocating the slide pins in the horizontal direction with respect to the sheet surface. However, even when the slide movement in the horizontal direction is imparted to the adhesive sheet, it is difficult to weaken the adhesive strength in a short

period.

Further, the abovementioned chips which are processed in a state that the thickness is decreased to approximately several tens μm are liable to be extremely easily cracked and hence, various designs or considerations are required in peeling these thin chips from the adhesive sheet, unlike peeling thick chips from an adhesive sheet.

Accordingly, it is an object of the present invention to provide a technique which can speedily peel extremely thin chips laminated to an adhesive tape without generating cracks or chippings.

The abovementioned object, other objects and novel features of the present invention will become apparent from the description of this specification and attached drawings.

To briefly explain a summary of a representative invention among inventions disclosed in this specification, it is as follows.

A manufacturing method of a semiconductor device according to the present invention includes the steps of:

(a) preparing a semiconductor wafer having an integrated circuit formed over a main surface thereof as well as an adhesive tape having a diameter larger than a diameter of the semiconductor wafer and having a surface on which an adhesive agent is applied;

(b) laminating the adhesive tape to a back surface of the semiconductor wafer and, thereafter, dividing the semiconductor wafer into a plurality of semiconductor chips by dicing; and

(c) peeling the semiconductor chips from the adhesive tape in such a manner that a vibrator is brought into contact with a back surface of the adhesive tape while applying a tension in a horizontal direction to a surface of the adhesive tape to which the plurality of semiconductor chips are laminated, and longitudinal vibrations having a frequency within a range of 1kHz to 100kHz and an amplitude within a range of 1 μ m to 50 μ m are applied to the semiconductor chips to be peeled out of the plurality of semiconductor chips and the adhesive tape disposed below the semiconductor chips by way of the vibrator.

DESCRIPTION OF THE PREFERRED EMBODIMENTS

Preferred embodiments of the present invention are described in detail in conjunction with attached drawings hereinafter. In all drawings that are served for explaining the embodiments, the same symbols are given to identical parts and their repeated explanation is omitted.

(Embodiment 1)

This embodiment is provided to be applied to the manufacture of a stacked package which mounts a plurality of chips three-dimensionally on a printed wiring board. A manufacturing method of the stacked package is explained in order of steps in conjunction with Fig. 1 to Fig. 23.

First of all, an integrated circuit is formed over a main surface of a wafer 1A made of single crystal silicon shown in Fig. 1 in accordance with a well-known manufacturing process as shown in Fig. 1 and, thereafter, an electric test is performed by bringing probes into contact with bonding pads 2 on a plurality of chip forming regions 1A' which are defined by a grid-like scribe lines so as to judge whether respective chip forming regions 1A' are defective or non-defective.

Next, as shown in Fig. 2, a back grind tape 3 for protecting the integrated circuit is laminated to the main surface side of the wafer 1A. A back surface of the wafer 1A is ground using a grinder in this state and, thereafter, a damage layer which

is generated by grinding on the back surface of the wafer 1A is removed by a method such as wet etching, dry polishing, and plasma etching thus decreasing a thickness of the wafer 1A to 100 μm or less, for example, approximately 50 μm to 90 μm . Although the method such as the abovementioned wet etching, dry polishing, plasma etching and the like exhibits the low processing speed which advances in the thickness direction of the wafer compared to the grinding speed of grinding using a grinder, damage to the inside of the wafer caused by these methods is small compared to the grinding using the grinder and, at the same time, the damage layer which is generated in the inside of the wafer by grinding using the grinder can be removed thus bringing about an advantageous effect that the wafer and the chips are hardly cracked.

Next, after removing the back grind tape 3, as shown in Fig. 3, a dicing tape 4 is laminated to the back surface of the wafer 1A and a peripheral portion of the dicing tape 4 is fixed to a wafer ring 5 in such a state. The dicing tape 4 is formed by applying an ultraviolet (UV) curing type adhesive agent which is cured by the irradiation, with ultraviolet rays, of a surface of a resin film made of polyolefin (PO), polyvinylchloride (PVC), polyethylene terephthalate (PET) and cutting the resin film having a circular shape.

Next, the wafer 1A is divided into a plurality of chips 1 by dicing the wafer 1A using a dicing blade 6 as shown in Fig. 4. Here, to leave the respective divided chips 1 on the dicing tape 4, the dicing tape 4 is not cut completely. Subsequently,

the dicing tape 4 is irradiated with ultraviolet rays in this state so as to harden an adhesive agent applied to the dicing tape 4 whereby the adhesiveness of the adhesive agent is lowered. Accordingly, the chips 1 can be easily peeled from the dicing tape 4 and, at the same time, the chips 1 which are once peeled from the dicing tape 4 in the chip peeling step described later are difficult to be adhered to the dicing tape 4 again.

Next, as shown in Fig. 5 (a plan view) and Fig. 6 (a cross-sectional view), a pusher plate 7 is arranged above the dicing tape 4 which is fixed to the wafer ring 5 and an expander ring 8 is arranged below the dicing tape 4. Then, as shown in Fig. 7, the pusher plate 7 is pushed to an upper surface of the wafer ring 5 and, at the same time, a peripheral portion of the back surface of the dicing tape 4 is pushed upwardly by the expander ring 8. Due to such a constitution, the dicing tape 4 receives a strong tension in the direction from the center portion to the peripheral portion so that the dicing tape 4 is stretched without being slackened.

Next, in such a state, the expander ring 8 is positioned above a stage 101 of a chip peeling device 100 shown in Fig. 8 and the dicing tape 4 is held horizontally. In the inside of the stage 101, a suction block 102 in which a vibrator 110 which oscillates the longitudinal vibrations is incorporated is arranged. The suction block 102 is configured to be movable in the horizontal direction as well as in the vertical direction using a driving mechanism not shown in the drawing.

Fig. 9 is an enlarged cross-sectional view of the vicinity

of an upper end portion of the abovementioned suction block 102. On a peripheral portion of an upper surface of the suction block 102 which faces the back surface of the dicing tape 4 in an opposed manner, end portions on one side of a plurality of suction openings 103 are arranged. The pressure inside these suction openings 103 is reduced by a suction mechanism not shown in the drawing.

On a center portion of an upper surface of the suction block 102, a window hole 104 which allows an upper end portion (an exchange head 111a) of the vibrator 110 to pass therethrough is formed. The vibrator 110 is moved vertically independently from the suction block 102 by a drive mechanism not shown in the drawing, wherein when a distal end of the head 111a which projects above the window hole 104 is brought into contact with the back surface of the dicing tape 4, the longitudinal vibrations in the vertical direction are imparted to one chip 1 to be peeled and the dicing tape 4 disposed below the chip 1 to be peeled.

Above the dicing tape 4 which is positioned at the stage 101, a suction collet 105 which is supported on a moving mechanism not shown in the drawing is arranged. At a center portion of a bottom surface of the suction collet 105, one end portion of a suction opening 106 whose pressure is reduced by a suction mechanism not shown in the drawing is arranged. Due to such a constitution, it is possible to selectively suck and hold one chip 1 which constitutes an object to be peeled.

Fig. 10 is a composite view which is constituted of a side view with a part broken away of the vibrator 110 which is incorporated into the suction block 102 of the abovementioned

chip peeling device 100, a view which expresses the relationship between a displacement of vibration in the longitudinal direction which resonates with the vibrator 110 and a position of the vibrator 110, and a view which expresses the relationship between an amplitude of vibration in the longitudinal direction which resonates with the vibrator 110 and the position of the vibrator 110. Fig. 11 is a side view with a part broken away of a vibrator body 112 of the vibrator 110.

The vibrator 110 is constituted of the vibrator body 112 and a resonance part 113. The resonance part 113 is a portion which resonates with the longitudinal vibrations which are generated by a piezo-electric element 114 incorporated into the resonance part 113 and amplifies an amplitude thereof. The resonance part 113 is designed such that a length in the direction (the vertical direction in the drawing) that the longitudinal vibrations propagate become $1/2$ of a wavelength of the longitudinal vibration. For example, with respect to a case shown in Fig. 10, when the amplitude of the longitudinal vibrations at an end portion of the piezo-electric element 114 which constitutes a vibration generating source by the piezo-electric element 114 is $3\mu\text{m}$, the amplitude at a portion of the head 111a is approximately $15\mu\text{m}$. To obtain such an amplitude of vibration, it is desirable to set a thickness of piezo-electric element 114 (a height of the piezo-electric element 114 along the vertical direction in Fig. 10) shorter than the wavelength of the longitudinal vibration. Further, it is preferable to set a diameter of the head 111a smaller than

a diameter of the piezo-electric element 114.

The vibrator body 112 is a portion which vibrates by resonating with the longitudinal vibrations amplified by the resonance part 113, wherein the vibrator body 112 is replaceably mounted on the resonance part 113 by fixing a flange 115 of the vibrator body 112 using a clamp 116, a holder 117 and a seal 118. To minimize the attenuation of the longitudinal vibrations, the flange 115 which is used for mounting the vibrator body 112 on the resonance part 113 is arranged at a node portion of the longitudinal vibration.

The vibrator body 112 is designed such that a length thereof in the direction that the longitudinal vibrations propagate becomes $1/2$ of the wavelength of the longitudinal vibration, while a length of the whole vibrator 110 which is formed by coupling the resonance part 113 to the vibrator body 112 is set to agree with 1 wavelength of the longitudinal vibration.

Although the length of the vibrator body 112 is not limited to $1/2$ of the wavelength of the longitudinal vibration, to increase the amplification ratio of the vibration, it is preferable to set the length such that a distal end of the exchange head 111a is positioned at a position of a side of the vibration or in the vicinity of the side of the vibration. It is also preferable to set the distal end of the exchange head 111a at least at a position where the amplitude of the longitudinal vibration becomes larger than an amplitude of the vibration which is oscillated from the end portion of the piezo-electric element

114. Further, the length of the vibrator body 112 may be set to a length which is obtained by adding a length which is integer times larger than the wavelength to the length which is $1/2$ of the wavelength. However, to miniaturize the whole device and to obtain the proper amplification ratio of vibration, it is preferable to set the length of the vibrator body 112 to the length which is equal to or in the vicinity of $1/2$ of the wavelength.

The exchange head 111a which is fixed to the distal end portion of the vibrator body 112 using screws is a portion which is brought into contact with the abovementioned dicing tape 4 and applies the longitudinal vibration to the dicing tape 4. With respect to the exchange head 111a, an exchange head having an optimum size is selected corresponding to the size of the chip 1 and the like. Since the distal end portion of the vibrator body 112 on which the exchange head 111a is mounted corresponds to a position where the amplitude of the longitudinal vibration becomes maximum, it is possible to efficiently apply the longitudinal vibration to the dicing table 4.

The vibrator 110 having the abovementioned constitution can cope with plural types of chips 1 by merely replacing the exchange head 111a and hence, it is possible to use the same vibrator body 112 and the resonance part 113 irrespective of the type of the chip 1 whereby the manufacturing cost of the chip peeling device 100 can be reduced. Further, since it is possible to use the same vibrator body 112 and the resonance part 113 irrespective of the type of the chip 1, there is no

possibility that the wavelength and the amplitude of the longitudinal vibrations become fluctuated for every type of chip 1 due to the dimensional irregularities of the vibrator body 112 and the resonance part 113.

The constitution of the vibrator 110 is not limited to the constitution described in this embodiment. However, the vibrator 110 of this embodiment can generate the vibrations of high frequency with low energy by amplifying the vibrations generated by the vibration source such as the piezo-electric element 114 in resonance with the vibrator 110 and, at the same time, it is possible to suppress the application of vibrations in the lateral direction. By suppressing the application of vibrations in the lateral direction, it is possible to prevent the occurrence of the displacement in the lateral direction or the rotational displacement of the chip 1 at the time of applying the vibrations to the chip 1 and hence, in the ensuing pellet-bonding step, it is possible to prevent the occurrence of defects attributed to the mounting of the chip 1 in a displaced manner from the given position.

Peeling of the chip 1 using the abovementioned chip peeling device 100 is performed at the timing shown in Fig. 12. To peel the chip 1 in accordance with the timing shown in the drawing, first of all, as shown in Fig. 13, the suction block 102 is elevated so as to bring an upper surface of the suction block 102 into contact with the back surface of the dicing tape 4 which is positioned below the chip 1 to be peeled and to suck the dicing tape 4. Here, by slightly pushing up the suction block 102 (by

approximately 400 μm , for example), it is possible to further apply a tension to the dicing tape 4 to which a tension in the horizontal direction is applied by the abovementioned pusher plate 7 and the expander ring 8.

Further, simultaneously with the elevation of the suction block 102, the suction collet 105 is lowered to bring a bottom surface thereof into contact with an upper surface of the chip 1 to be peeled so as to suck the chip 1 and, at the same time, to lightly push the chip 1 downwardly. Since the peeling of the chip 1 is performed in an extremely short time (usually, approximately 0.05 seconds to 0.5 seconds), by preliminarily fixing the chip 1 by pushing with the suction collet 105 before applying the vibrations to the dicing tape 4, it is possible to prevent the chip 1 peeled from the dicing tape 4 from jumping out due to the vibration.

Then, in this state, the vibrator 110 is operated (timing a in Fig. 12). Here, the head 111a of the vibrator 110 is not brought into contact with the back surface of the dicing tape 4.

With respect to the abovementioned vibrator 110, the preferred oscillation frequency falls within a range of 1 kHz to 100 kHz and the preferred amplitude falls within a range of 1 μm to 50 μm . Although it is possible to peel the chip 1 even when the frequency is less than 1 kHz, it takes a long time for peeling and hence, it is not practical to adopt such a frequency. In the same manner, it is also possible to peel the chip 1 even when the amplitude is less than 1 μm . However, it also takes

a long time for peeling. On the other hand, when the frequency exceeds 100 kHz, side effects including a side effect of increase in a heat value of the dicing tape 4 attributed to the vibration energy become apparent. Further, when the amplitude exceeds 50 μm , particularly when the chip 1 is extremely thin, cracks occur or the integrated circuit is damaged. According to this embodiment, the oscillation frequency of the vibrator 110 is set to 60kHz and the amplitude of the vibrator 110 is set to 10 μm .

Next, as shown in Fig. 14, the vibrator 110 is elevated so as to bring the head 111a into contact with the back surface of the dicing tape 4 which is positioned below the chip 1 to be peeled (timing b in Fig. 12). At this point of time, by slightly pushing the vibrator 110 upwardly (for example, 400 μm), it is possible to apply a stronger tension in the horizontal direction to the dicing tape 4 (timing b-c in Fig. 12).

When the vibrating head 111a comes into contact with the back surface of the dicing tape 4, the longitudinal vibrations in the direction perpendicular to the surface of the dicing tape 4 are applied to the dicing tape 4 and the chips 1.

Here, the explanation is made with respect to a mechanism of chip peeling brought about by the application of vibration from the head 111a formed over the distal end of the vibrator 110.

The head 111a repeats the high-speed elevation and the lowering in a short time due to the vibrations thereof. At the time of elevating the head 111a, due to the pressure generated

by the head 111a, the upward movement is applied to the dicing tape 4 and the chip 1. When the head 111a finishes the elevation movement thereof, the head 111a rapidly turns into the downward movement. During the downward movement of the head 111a, since the movement is performed at a high speed and the change of speed from the upward movement to the lower movement is performed suddenly, the dicing tape 4 and the chips 1 cannot follow the movement of the head 111a and there exists the possibility that the dicing tape 4 and the chip 1 are separated from the head 111a. During the downward movement of the head 111a, while the chip 1 tries to continue the upward movement in accordance with the law of inertia, the strong tension is applied to the dicing tape 4 and hence, the dicing tape 4 tries to restore a state having a smaller surface area due to the tension whereby an acceleration in the downward direction acts on the dicing tape 4. In this manner, due to the inertia which the chip 1 possesses during the downward movement of the head 111a and the acceleration which is generated due to the tension applied to the dicing tape 4, a force which separates the chip 1 and the dicing tape 4 from each other is exerted.

The peeling of the chip 1 from the dicing tape 4 starts at an end portion of the chip 1 where the tension applied to the dicing tape 4 assumes the largest value and the separation sequentially advances in the direction toward the inside of the chip 1.

To impart the sufficient movement to the chip 1 during the elevation movement of the head 111a, it is necessary to elevate

the head 111a at a high speed. To ensure a sufficient value with respect to the acceleration which is generated in the dicing tape 4 during the downward movement of the head 111a, it is necessary to preliminarily apply the strong tension to the dicing tape 4. To exert the sufficient acceleration which is generated by the tension applied to the dicing tape 4, it is necessary for the dicing tape 4 to change the speed from the upward movement to the downward movement and to perform the downward movement at a high speed with energy which prevents the dicing tape 4 from following the head 111a. Further, to accelerate the peeling of the chip 1 due to such a mechanism, it is necessary to repeat the upward movement and the downward movement of the head 111a as many times as possible within a short period.

Next, as shown in Fig. 15, the chip 1 which is peeled from the dicing tape 4 is pulled upwardly after being sucked and held by the collet 105. Simultaneously, the operation of the vibrator 110 is stopped (timing d in Fig. 12).

A given time ranging from a point of time that the application of the vibrations to the dicing tape 4 is started to a point of time that the chip 1 is pulled upwardly (timing b to timing d in Fig. 12) differs depending on many factors including a size and a thickness of the chip 1, a material of the dicing tape 4 and a type of the adhesive agent, the frequency and the amplitude of the vibrations applied to the dicing tape 4, the magnitude of the tension applied to the dicing tape 4, a size and a shape of the head 111a and the like. Accordingly, the timing for pulling the chip 1 upwardly is preliminarily

calculated based on experiments.

Further, in this embodiment, simultaneously with the peeling of the chip 1 from the dicing tape 4, the application of vibrations to the dicing tape 4 is stopped. This is because when the application of the vibrations of a high frequency to the portion of the dicing tape 4 from which the chip 1 is removed is continued, due to heat generated by the friction between the head 111a and the dicing tape 4, the dicing tape 4 is melt and hence, there exists a possibility that the head 111a is contaminated or the tension applied to the dicing tape 4 is lowered.

To stop the vibration of the vibrator 110 in synchronism with the pulling up of the chip 1 by the suction collet 105, for example, a change of a load which is applied to the head 111a by the suction collet 105 which fixes the chip 1 by pushing may be detected based on a change of current, a change of voltage, a change of impedance and the like. Here, when the peeling of the chip 1 progresses to some extent, the chip 1 can be peeled from the dicing tape 4 using only a suction force which the suction collet 105 generates for sucking the chip 1 and hence, the vibration of the vibrator 110 may be stopped immediately before pulling the chip 1 upwardly.

Next, as shown in Fig. 16, the vibrator 110 and the head 111a are lowered (timing e in Fig. 12). Due to the steps which are performed heretofore, a process for peeling one chip 1 from the dicing tape 4 is completed.

Then, the suction collet 105 transports the chip 1 peeled

from the dicing tape 4 to a next process (pellet-bonding process) and returns to the chip peeling device 100. Thereafter, in accordance with the steps explained in conjunction with Fig. 13 to Fig. 16, the operation for peeling the next chip 1 from the dicing tape 4 is started and, thereafter, the non-defective chip 1 on the dicing tape 4 is peeled in accordance with the similar steps.

The given time ranging from the point of time that the vibration is applied to the dicing tape 4 to the point of time that the chip 1 is pulled upwardly may be shortened by optimizing the size and the shape of the head 111a.

In general, it is desirable that an area of the upper surface of the head 111a (the face which is brought into contact with the back surface of the dicing tape 4) is slightly smaller than an area of the chip 1 to be peeled. When the area of the upper surface of the head 111a is larger than the area of the chip 1, the dicing tape 4 in the vicinity of a peripheral portion of the chip 1 is sandwiched from both sides by the chip 1 and the head 111a and hence, the progress of peeling heading toward the inside from the peripheral portion of the chip 1 is delayed. On the other hand, when the area of the upper surface of the head 111a is excessively smaller than the area of the chip 1, at the time of applying the vibrations to the dicing tape 4, it is impossible to concentrate a sufficient stress on an interface of the end portion of the chip 1 which constitutes a peeling start point of the dicing tape 4 and the chip 1 and hence, a strong bending stress is applied to the chip 1 whereby

the chip 1 may be cracked. From the abovementioned viewpoint, it is understood that a shape which allows point contact with the dicing tape 4 such as a projecting pin, for example, is not suitable as the shape of the head 111a. Although there exists no particular limitation, in this embodiment, when the size of the chip 1 is within a range of 3 mm squares to 7 mm squares, the head 111a having the area of the upper end portion which is 2.5 mm squares can be used. On the other hand, when the size of the chip 1 is within a range of 6 mm squares to 10 mm squares, the head 111a having the area of the upper end portion which is 4 mm squares can be used.

Further, as in the case of the head 111b shown in Fig. 17, for example, fillets may be formed over the peripheral portion of the upper surface or a radius of curvature (R_1) of the peripheral portion may be set smaller than a radius of curvature (R_2) of a center portion of the upper surface ($R_1 < R_2$). By adopting such a shape, while it is possible to efficiently apply the vibrations to the chip 1 using the center portion of the head 111b having the large radius of curvature, it is also possible to reduce a bending stress generated in the inside of the chip 1. Further, the vibrations may be applied in a state that a peripheral portion having a radius of curvature slightly smaller than the radius of curvature of the center portion of the head is formed around the center portion of the head 111b and the peripheral portion of the head is arranged inside the end portion of the chip 1. In this case, it is possible to sufficiently concentrate a peeling stress on an interface at the end portion of the chip 1 which

constitutes the peeling start points of the dicing tape 4 and the chip 1 whereby the peeling is facilitated and, at the same time, the progress of the peeling heading toward the inside from the peripheral portion of the chip 1 is enhanced. Accordingly, the chip 1 can be peeled in a short period. For example, as in the case of a head 111c shown in Fig. 18, even when the peripheral portion of the upper surface is chamfered, it is possible to obtain the substantially same advantageous effect.

Further, the shape of the center portion of the head having the large radius of curvature is not limited to the flat shape shown in Fig. 17 and Fig. 18. Provided that the radius of curvature of the center portion of the head is larger than the radius of curvature of the peripheral portion of the head, a shape having a convex-shape curvature may be adopted. Further, as in the case of a head 111d shown in Fig. 19, fillets may be formed over the periphery of the upper portion and a recess may be formed in the center portion. Due to such a shape, as shown in Fig. 20, when the back surface of the dicing tape 4 is pushed upwardly by the head 111d, the whole chip 1 is warped in conformity with the recess of the head 111d and hence, the chip 1 can increase the strength compared to a case in which the chip 1 has a flat shape and whereby the chip 1 is hardly cracked even when the high vibration energy is applied to the chip 1. Further, since the peripheral portion of the chip 1 is warped, a peeling angle (θ) of the dicing tape 4 with respect to the chip 1 is increased, the chip 1 can be more easily peeled off. When the recess is provided to the center portion of the head 111d, a bottom surface

of the suction collet 105 may be formed into a convex shape in conformity with the recess of the head 111d.

Further, when the chip 1 is extremely small, when a portion having a large radius of curvature is provided to the center portion of the head 111b, a distance from the peripheral portion of the head 111b to the end portion of the chip 1 becomes small and hence, it is difficult to concentrate the sufficient stress on the interface of the end portion of the chip 1 which constitutes the peeling start point. Accordingly, in such a case, it is possible to use the head 111b having the small radius of curvature at the center portion without forming the center portion having the large radius of curvature on the head 111b.

As shown in Fig. 21, the chip 1 which is transported to the pellet-bonding process is mounted on a printed wiring board 11 by way of an adhesive agent 10 and the like and is electrically connected with electrodes 13 formed over the printed wiring board 11 by way of Au wires 12.

Next, as shown in Fig. 22, a second chip 14 is stacked over the chip 1 which is mounted on the printed wiring board 11 by way of the adhesive agent 10 and is electrically connected with electrodes 16 formed over the printed wiring board 11 by way of Au wires 15. The second chip 14 is a silicon chip on which an integrated circuit different from the integrated circuit of the chip 1 is mounted. The second chip 14 is peeled from the dicing tape 4 by the abovementioned method and is transported to the pellet-bonding step where the second chip 14 is mounted on the chip 1.

Thereafter, the printed wiring board 11 is transported to a mold step where, as shown in Fig. 23, a stacked package 18 is substantially completed by sealing the chips 1, 14 with a mold resin 17.

(Embodiment 2)

The peeling of the chip 1 may be performed in accordance with the timing shown in Fig. 24. To peel the chip 1 in accordance with the timing shown in the drawing, first of all, as shown in Fig. 25, the suction block 102 is elevated so as to bring an upper surface of the suction block 102 into contact with the back surface of the dicing tape 4 which is positioned below the chip 1 to be peeled and to suck the dicing tape 4. Here, in the abovementioned embodiment 1, the suction collet 105 is lowered to bring the bottom surface thereof into contact with the upper surface of the chip 1 to be peeled. In this embodiment, however, the suction collet 105 is lowered to the vicinity of the upper surface of the chip 1 and is stopped without bringing the bottom surface of the suction collet 105 into contact with the chip 1 (timing a in Fig. 25).

Next, as shown in Fig. 26, the vibrator 110 is elevated to bring the head 111a into contact with the back surface of the dicing tape 4 and, at the same time, the application of vibration is started (timing f in Fig. 24). At this point, since the suction collet 105 is not brought into contact with the chip 1, the vibration resistance is small and hence, it is possible to efficiently apply the vibrations of the larger energy at the peeling starting stage.

Next, as shown in Fig. 27, the elevation (upward pushing) of the vibrator 110 is continued while applying the vibrations to the dicing tape 4 so as to bring the upper surface of the chip 1 into contact with the bottom surface of the suction collet 105 before the chip 1 is completely peeled from the dicing tape 4 and, thereafter, the chip 1 is sucked and held by the suction collet 105 (timing b in Fig. 24). Subsequently, the elevation of the vibrator 110 is stopped (timing c in Fig. 24). Simultaneously with the complete peeling of the chip 1 from the dicing tape 4 or immediately before the complete peeling of the chip 1, the suction collet 105 is pulled upwardly together with the chip 1 and, at the same time, the operation of the vibrator 110 is stopped (timing d in Fig. 12).

When the chip 1 is peeled in accordance with the abovementioned timing, before the suction collet 105 and the chip 1 are brought into contact with each other, the application of vibrations by the vibrator 110 is started and hence, the resistance against the vibration can be reduced whereby the starting and the progress of the peeling can be enhanced. Further, even after the application of vibration by the vibrator 110 is started, the elevation of the vibrator 110 is continued and the chip 1 and the suction collector 105 are brought into contact with each other before the chip 1 is completely peeled from the dicing tape 4 and hence, the chip 1 is held. Accordingly, it is possible to prevent the peeled chip 1 from falling from the dicing tape 4.

Although the inventions made by inventors of the present

inventions have been specifically explained in conjunction with the abovementioned embodiments, it is needless to say that the present invention is not limited to the abovementioned embodiments and various modifications can be made without departing from the gist of the present inventions.

Although the longitudinal vibration is applied to the back surface of the dicing tape in the abovementioned embodiments, it is possible to apply a standing wave which is referred to as an S mode to the back surface of the dicing tape. In this case, it is necessary to design the application of the standing wave such that the standing wave is selectively applied only to the vicinity of the chip to be peeled.

Although the explanation has been made with respect to the case in which the thickness of the wafer is reduced to several ten μm in the abovementioned embodiments, the thickness of the wafer is not limited to such a value and the present invention is applicable to a wafer having a smaller thickness or a wafer having a larger thickness.

To briefly recapitulate the advantageous effects obtained by the representative inventions among the inventions disclosed in this specification, they are as follows.

At the time of dicing the semiconductor wafer laminated to the adhesive tape into the plurality of semiconductor chips and then, peeling the respective semiconductor chip from the adhesive tape, even when the semiconductor chips are extremely thin, it is possible to speedily peel the semiconductor chips without generating cracks or chippings.
